A Final Report Prepared for the U.S. Fish and Wildlife Service, Ecological Services Office, Environmental Contaminants Division.

2N23,9520005

INTRODUCTION

Selenium is bioaccumulated in organisms at each successive level of the detrital food chain in connected backwater lakes along the lower Colorado River (Radtke et al. 1988, Lusk 1993). Elevated selenium levels first occur in aufwuchs and the organic layer at the surface of the sediment on the pond bottom (Lusk 1993, Villegas 1997). Selenium bioaccumulates in organisms that feed on aufwuchs and detritus (benthic insects, crayfish, and clams) and reaches still higher levels in fish that feed on these organisms. The highest levels are found in fish eating birds (Rusk 1991, Lusk 1993, Martinez 1994, Welsh and Maughan 1994). In contrast, levels are only slightly elevated in plants and aquatic plant eating birds, such as coots. Based on these data, researchers initially concluded that only organisms that feed on aquatic insects, crayfish, clams or fish are in danger of having elevated levels of selenium in their tissues (Rusk 1991, Lusk 1993, Martinez 1994, Welsh and Maughan 1994). Birds, other than those that eat fish, were not initially considered to be at risk of accumulating selenium. However, Martinez (1994) analyzed selenium levels in a single nest of nighthawk eggs and found levels were similar to those in the eggs of fish eating birds.

Prior to the initiation of this study, much consideration was given to how the selenium levels in the nighthawk eggs sampled by Martinez (1994) had become elevated. The most logical source of the selenium in the eggs appeared to be the benthic insects from the backwaters that had metamorphosed from the aquatic to the aerial phase of their life cycle. Birds that fed on these insects might accumulate selenium in their tissues and pass it on into their eggs. Therefore, any bird feeding on aquatic insects emerging from

the backwaters and becoming aerial would be at risk for accumulating selenium. Thus, we decided to study selenium levels in five passerine bird species along the lower Colorado River.

The objectives of the study were to:

 Evaluate selenium levels in Neotropical migrants and riparian obligate birds on Imperial National Wildlife Refuge (Imperial NWR).

2. Evaluate selenium-induced reproductive impacts on birds along the lower Colorado River.

METHODS

Sites Sampled and Species Collected

Samples were collected from three sites on Imperial NWR and one site near Mittry Lake Wildlife Management Area (Mittry Lake). Species were collected based on availability across sites. We collected 10 adult individuals from four passerine species at Imperial NWR and one from Mittry. Samples of eggs from the same species were also collected. Species collected included red-winged blackbird (<u>Agelaius phoeniceus</u>), western kingbird (<u>Tyranus verticalis</u>), cliff swallow (<u>Hirundo pyrrhonota</u>), song sparrow (<u>Melospiza melodia</u>), and verdin (<u>Auriparus flaviceps</u>). Inadvertantly a few bank swallows (<u>Riparia riparia</u>) and tree swallows (<u>Iridoprocne bicolor</u>) that were flocking with cliff swallows were also collected.

Sample Collection and Preparation

Birds were collected throughout the breeding season, April to August 1995. Therefore, we are confident that the levels we measured represent levels acquired on the breeding grounds. One of three collection methods was used; a 20-gauge shotgun loaded with steel shot, a BB gun, or hand capture. Nests from which birds were hand captured were located during the day and then revisited at night and the birds captured on the nest. Specimens were kept on wet ice, for no more than six hours, until dissection. Whole birds (feathers, bill, feet and GI tract removed) were weighed. Livers were removed with a stainless steel scalpel, individually weighed, and individually wrapped in aluminum foil. Between dissections, all instruments were washed with distilled, deionized water and rinsed with hexane to prevent cross contamination. Eggs were measured, the contents removed and placed in chemically cleaned jars, and frozen in accordance with the guidelines of the Patuxent Analytical Control Facility (PACF). Egg shells were not analyzed. Most eggs were collected from nests on Imperial NWR but two song sparrow eggs were obtained from Havasu NWR. Samples were stored in a freezer until analysis at the Research Triangle Institute. Egg collection was completed in 1996.

Overall nest success and incidence of embryo malformations in a colony of cliff swallows was monitored from March to June 1997 at Mittry Lake. We carefully examined all chick mortalities from this population for indications of abnormalities. We also attempted to evaluate nest success and incidence of embryonic malformations for the other four species during March to June 1998. However, nesting was limited during that year and we could not locate sufficient nests for evaluation.

Selenium Analysis

Selenium analyses were conducted by Research Triangle Institute (RTI), Research Triangle Park, North Carolina; a contract laboratory of the PACF. Selenium was analyzed using Graphite Furnace Atomic Absorption (GFAA). Tissue samples were homogenized using a food processor. A portion of the tissue sample was freeze-dried for determination of moisture content and ground to 100 mesh. Digestion for GFAA measurement was conducted using a CEM microwave oven. From 0.25 to 0.5 g of freeze-dried sample was heated in a capped 120 ml Teflon vessel in the presence of 5 ml of Baker Instra-Analyzed nitric acid for three minutes at 120 watts, three minutes at 300 watts, and fifteen minutes at 450 watts. The residue was then diluted to 50 ml with laboratory pure water. GFAA measurements were made using a Perkin-Elmer Zeeman 3030 or 4100ZL atomic absorption spectrometer.

Quality Assurance/Quality Control

Quality assurance used by RTI for the chemical determinations included the analysis of duplicate samples, procedural blanks, analysis of standard reference materials (i.e., dogfish liver {NRCC DOLT-2} and lobster hepatopancreas {NRCC TORT-1}, and spike recoveries. PACF monitored and approved all quality assurance/quality control methodology.

Statistical Analysis

Range and standard error of the arithmetic mean are reported as measures of dispersion. Bartlett's test was used to determine if variances were equivalent. Selenium levels in the whole body tissues of the five principle species were analyzed with analysis of

variance (ANOVA) and then by multiple comparisons of means with the Tukey-Kramer procedure (Sokal and Rolf 1981). Selenium levels in the livers (cliff swallow, redwing blackbird and western kingbird) and eggs (verdin, cliff swallow, redwing blackbird, and western kingbird) were analyzed with ANOVA and then by multiple comparisons of means with the Tukey-Kramer procedure. The levels of selenium among tissues (whole body, liver and egg) of each passerine species were analyzed with a t-test (two tissues) or ANOVA followed by multiple comparisons of the means with the Tukey-Kramer procedure (three tissues). All statistical tests were considered significant at $P \le 0.05$.

STUDY AREA

The Lower Colorado River includes approximately 453 km of the Colorado River from Davis Dam to the United States-Mexico international border. Average annual precipitation along the Lower Colorado River is 10-13 cm. Average temperatures ranges from 21.1° C to 4.4°C in the winter and 40.6° C to 22.7° C the summer.

Imperial NWR is one of four national wildlife refuges located along the lower Colorado River. This refuge is located approximately 105 km north of the international boundary and includes the lower Colorado River along the Arizona-California border (Martinez 1994). Imperial NWR encompasses a total of 10,706 ha. Wetlands, lakes and marshes comprise 4,324 hectares, 5,630 ha are associated with desert and mountains, and 96 ha are dedicated to croplands (Lusk 1993). The Refuge was established in 1941 to mitigate the effects of channelization and to manage wildlife attracted to the backwaters formed after the construction of Imperial Dam (Rosenberg et al. 1991). This refuge

protects two unique types of environment: the desert and a variety of wetland and riparian environments associated with the lower Colorado River. The desert areas are characterized by vegetation typical of the Lower Colorado River Valley Sonoran Desert including Velvet Mesquite (<u>Prosopis velutina</u>), Blue Paloverde (<u>Cercidium floridum</u>), Desert Ironwood (<u>Olneya tesota</u>), Creosote (<u>Larrea tridentata</u>), Salt Bush (<u>Atriplex</u> <u>canescens</u>), Graythorn (<u>Ziziphus obtusifolia</u>), Bur Sage (<u>Ambrosia deltoidea</u>), Big Galleta (<u>Hillaria rigida</u>), Beavertail Cactus (<u>Opuntia basilaris</u>), Ocotillo (<u>Fouguieria splendens</u>), Teddybear Cholla (<u>Opuntia bigelovii</u>), Hedgehog Cactus (<u>Echinocerus engelmannii</u>), and Desert Agave (<u>Agave deserti</u>).

Description of wetland areas

Backwaters on Imperial NWR have a detrital-silt substrate underlain by sand and gravel and surrounded by dense, monotypic stands of cattail (<u>Typha latifolia</u>.) bulrush (<u>Scirupus validus</u>.) or giant reed (<u>Arundo donaxi</u>) depending on water depth and slope. The predominant submergant is spiny naiad (<u>Najas marina</u>) but sago pondweed (<u>Potamogeton pectinatus</u>), water milfoil (<u>Myriophyllum spp</u>.), macroalgae (<u>Chara spp</u>.) and coontail (<u>Ceratophyllum spp</u>.) are present along the edges of the wetlands. True seeps support no submerged aquatic macrophytes and are lined almost exclusively by cattails.

Almost all underwater surfaces are covered with a layer of yellowish-brown slimy aufwuchs, i.e., the combined assemblage of epipelic, epiphytic, and epizoic periphyton and suctorian cilieates (Cole 1994). During the summer, floating mats of filamentous algae

(mostly cyanophyta) (Kennedy 1979) are present in many of the backwaters. Seep lakes contain benthic algae and freshwater sponges that may be unique to these wetlands (Prieto 1998).

Mittry Lake is an ox-bow lake located between Imperial and Laguna Dams that receives water by way of a diversion from Imperial Reservoir. The lake is located approximately 29 km north of Yuma, Arizona. The Arizona Game and Fish Department, the United States Bureau of Reclamation, and the United States Bureau of Land Management manage Mittry Lake. Mesquite, Arrowweed (<u>Pulchea sercea</u>), Cottonwood (<u>Populus fremontii</u>), and saltcedar (<u>Tamarix pentandra</u>) dominate the riparian vegetation surrounding the lake. Cattails, bulrushes, and saltcedar dominate bank vegetation (Schluesner 1997).

RESULTS

Whole body samples were collected from each bird species. However, due to minimum one-gram weight requirements for sample analysis, livers were only collected from cliff swallows, red-winged blackbirds, and western kingbirds. Livers in verdins and song sparrows did not meet the one-gram minimum. Selenium levels are reported on a dry weight basis unless otherwise stated.

Each species accumulated selenium at different rates in individual tissues and eggs. For example, western kingbirds, had the highest levels of selenium in the eggs, while on average they were third in whole body levels and second in liver levels. Red-winged blackbirds had the second highest level in their eggs but had the highest levels in whole

bodies and livers (Table 1).

					Se D	ry Wt. (pp	m)	
Species	Collection Site	Date (1996)	Body	(n)	Range	Liver	(n)	Range
Cliff Swallow	Backwater	7/18 - 8/31	2.07	9	1.15 - 3.33	3.86	9	2.65 - 6.02
Blackbird	Seep Lake	6/2 - 6/12	4.67	10	1.19-4.82	12.30	10	5.05 - 19.2
Song Sparrow	Seep Lake	5/23 - 6/28	3.81	10	2.56-4.81	N/A	10	N/A
Verdin	Desert Upland	5/22 - 6/28	2.32	10	0.94 - 3.66	N/A	10	N/A
Kingbird	Farm Fields	5/22 -7/26	2.81	10	1.19 - 4.82	6.86	10	3.9 - 10.44

Table 1. Selenium levels in whole bodies and livers of five bird species from Imperial National Wildlife Refuge.

Selenium levels were not significantly different between eggs and whole bodies of verdins (t-test, df=15, P=0.144) and song sparrows (t-test, df=12, P=0878). However, selenium levels were significantly higher in livers than in whole bodies in tree swallows (t-test, df=4, P=0.0002) and bank swallows (t-test, df=2, P=0.372). Selenium levels were also significantly different between livers, whole bodies, and eggs in cliff swallows (ANOVA, P=<0.0002), red-winged blackbirds (ANOVA, P=<0.0001) and between livers and whole bodies in western kingbirds (ANOVA, P=<0.0002).

Selenium levels were generally higher in whole bodies and livers of females than in whole bodies and livers of males (Table 2). Exceptions were in western kingbirds where both levels were higher in males than females and in red-winged blackbirds where whole body levels were higher in males than females.

				V	Whole Bod	у		Liver	
Species	F (n)	M(n)	? (n)	F	М	?	F	М	?
Cliff Swallow	2	4	3	2.46	1.72	2.27	3.83	3.71	4.1
Red-Winged Blackbird	3	7	0	4.08	4.41	0	12.53	11.92	0
Song Sparrow	3	7	0	3.91	3.77	0	N/A	N/A	N/A
Verdin	2	3	5	3.15	1.92	2.23	N/A	N/A	N/A
Western Kingbird	2	8	0	2.54	3.9	0	6.02	6.94	0

Table 2. Arithmetic means of selenium concentrations (ppm, dry weight) in adult tissues by species and gender (n = number of birds analyzed, F=females, M=males and ?=birds of unknown sex).

Selenium levels in livers were always higher than those in whole bodies within a given species. Selenium levels in livers of red-winged blackbirds were about three times those in whole bodies.

Among Species Comparisons

Selenium levels in whole bodies of bank swallows and tree swallows did not differ from those in cliff swallows (t-test, df=9, p=0.306 and t-test, df=9, p=0.456), nor did they differ in livers of cliff swallows and tree swallows (t-test, df=10, P=0.407). Selenium levels were significantly higher in the whole bodies of red-winged blackbirds than those in the other species (ANOVA, P=0.0002). Levels were lowest in cliff swallows but differences were only significantly lower than those in red-winged blackbirds and song sparrows.

Selenium levels in the livers of cliff swallows, red-winged blackbirds, western kingbirds were significantly different (ANOVA, P<0.0001). Levels were significantly

higher in red-winged blackbirds than the other two species, but levels between the other two species were not significantly different from one another.

Eggs

A total of 30 eggs were collected during the early breeding season. Seven eggs were collected from cliff swallows, red-winged blackbirds, verdins, and western kingbirds. No song sparrow nests that contained eggs could be found on Imperial National Wildlife Refuge, but two eggs were obtained from Havasu NWR. All the eggs were near or at the level for chronic toxicity (Table 3).

Table 3. Selenium levels is eggs of five bird species from Imperial National Wildlife Refuge and Havasu National Wildlife Refuge.

	Imperial Nat	ional Wildlife	Refuge	Amt. Se	Havasu Nat	ional Wildlife	Refuge	Amt. Se
Species	Location	Date	(n)	Eggs	Location	Date	(n)	
Cliff Swallow	Backwater	4/12/96	7	2.56	N/A	N/A	N/A	N/A
Red-Winged	Seep Lake	5/1/96	7	4.54	N/A	N/A	N/A	N/A
Song Sparrow	N/A	N/A	N/A	N/A	Seep Lake	6/21/97	2	3.72
Verdin .	Desert	4/5/96	7	2.9	N/A	N/A	N/A	N/A
Western Kingbird	Farm Fields	6/21/96	7	5.99	N/A	N/A	N/A	N/A

Selenium levels in the eggs were significantly different among the five species (ANOVA, P<0.001). Levels were highest in the eggs of western kingbird and redwing blackbird and lowest in cliff swallows.

A total of 94 cliff swallow nests were monitored weekly. Seventy four of these nests contained eggs at some time during the study period. However, chicks were

produced in only seven nests. Many eggs were destroyed before they had the opportunity

to hatch (Table 4). In early June many nests were destroyed during causeway

construction. Only limited nesting occurred after that disturbance. Prior to that date,

mortalities appeared to result from intraspecific interactions.

Table 4. Status of Cliff Swallow Nests on the Mittry Wildlife Management Area during the Spring and Summer of 1997. Numbers refer to numbers of eggs (eg 3e), or fledglings (eg 3f). Additional letters define the special conditions of the eggs or fledglings (eg b=eggs present but broken and d=fledlings present but dead). A zero indicates the nest was empty and a D indicates that the nest that had been at this location during the previous sampling effort had been destroyed during the interval between samples.

DISCUSSION

Selenium was elevated to levels of concern in the tissues and eggs of all five bird species. Previous data has shown elevated selenium levels in fish eating birds and nighthawks. Our data now add red-winged blackbirds, song sparrows, western kingbirds, verdins, and cliff swallows to the list of potential species at risk. The fact that selenium levels were elevated in all of the birds studied, suggest most passerine birds along the

lower Colorado River face some risk of accumulating selenium.

Why are we concerned about the levels of selenium in tissues and eggs of these birds? Selenium levels of 3 ug/g dry weight in bird eggs is considered to be the threshold of concern for teratogenesis and levels in the livers of adults of >10 ug/g dry weight have been associated with adverse biological effects (Lemly 1993). Selenium levels in the livers of the birds we studied ranged from 2.7-10.4 ug/g dry weight and levels in their eggs ranged from 2.6-6.0 ug/g dry weight. Martinez (1994) had previously reported that levels in eggs and egg masses (unlaid eggs taken from the female reproductive tract) of several species of fish eating birds averaged from 8.7 to 10.3 ppm dry weight. It appears from these data that levels of selenium in the eggs of both passerine and fish eating species exceed those where there is risk of teratogenesis.

We had hypothesized that birds that were primarily insectivorous would have higher selenium levels in their tissues and eggs than those that generally feed upon seeds. This hypotheses was based on the assumption that passerine birds in the riparian corridor obtained selenium by feeding on the aerial stage in the life cycle of aquatic insects. Although the pathway through the aerial stage of aquatic insects is still the most plausible route for the entry of selenium into the diet of riparian birds, the hypothesis that birds that were primarily insectivorous would have the highest levels, was not substantiated.

There are several possible reasons why this hypothesis was not supported by the data. First, the source of the selenium could be other than that obtained through the ingestion of aquatic insects. While it is possible that there is a source of selenium, other than insects, there is no obvious alternative source. Soils in the study area are not

seleniferous and irrigation return flows do not contain elevated selenium levels (Welsh and Maughan 1994, Villegas 1997). Selenium levels in the water in the river and plants in the backwater are low and obtaining selenium directly from these sources would not result in the observed elevated levels in the birds. Therefore, it seems probable that aquatic insects are the source from which riparian birds obtain selenium.

Another possibility is that all of the bird species studied may have been primarily insectivorous at the time of the study. The study took place during the breeding season, when there are major energy and protein demands. During the period of egg laying, at least female birds take larger numbers of insects than during other periods because of the need for extra protein (Rosenberg et al. 1991). Since all the species studied were nesting during the study period, they may have been primarily feeding on insects.

A third possibility may be that some of the birds studied may have fed on insects that had lower selenium levels than those that emerged from the connected backwaters. For example, selenium levels in cliff swallows were lower in whole bodies, eggs, and livers than in any other species, even though cliff swallows are primarily insectivorous and were nesting adjacent to an area where the aquatic biota were known to have elevated selenium levels in their tissues (Schleusner 1997, Villegas 1997). We believe these low levels occurred because swallows foraged away from the location where they nested. In the morning, swallows left the nesting area by following a irrigation canal away from the river. In the evening they returned to the nesting area, from across the desert. These observations suggest that the birds from this particular nesting colony did not feed over the backwater areas adjacent to the nesting area and thus, may have minimized their

exposure to the elevated selenium levels in emerging insects.

We had also hypothesized that selenium levels would be highest in birds nesting beside backwater lakes, where there was more potential for exposure to insects that are known to have higher selenium levels in their tissues than those that emerge from seep lakes (Lusk 1993, Prieto 1997). Again the data did not support the hypothesis. Redwinged blackbirds that nested beside a seep lake consistently had higher selenium levels in their tissues than cliff swallows that nested beside a connected backwater lake. We believe these lack of differences in selenium levels result from a combination of the feeding location hypothesis presented for cliff swallows earlier and the fact the insects that emerge from the connected backwater disperse beyond the immediate location of the waters from which they emerge.

We had also hypothesized that birds that nested further from the river would have lower selenium levels in their tissues than those that nested adjacent to the river or the associated backwaters. Again the data did not support the hypothesis. Western kingbirds that nested the fartherest from the river had the highest selenium levels in their eggs. The failure of the data to support the hypothesis suggest either that insects disperse widely after emerging from the backwaters or that all of the birds studied foraged in the riparian corridor even though they nested outside that corridor. It appears that all of the bird species studied were exposed to selenium regardless of where they nested or their primary food source.

Selenium levels in most organisms are generally higher in liver than they are in eggs and higher in eggs than they are in whole bodies (Fairbrother and Fowles 1990,

Heinz et al. 1990, Martinez 1994). We also saw this trend in the birds that we studied. Levels varied among species but they were always highest in livers and lowest in whole bodies. Levels in eggs were generally more comparable to those in livers than those in whole bodies. Selenium levels in tissues generally reflect the rate of metabolic activity (Beilstein and Whagner 1987). The liver is an organ of active metabolism and excretion and thus selenium levels in the liver are generally higher than they are in most other tissues. The high metabolic activity that is required to produce eggs accounts for the high levels of selenium in eggs. Metabolic rates vary greatly in the several tissues of the body. Therefore, selenium levels in the whole bodies are generally lower than they are in the metabolically active tissues such as liver and eggs.

In the five species studied, females generally had higher selenium levels in whole bodies than did males, and in two of the three species where livers were taken, liver levels were also higher in females. However, female red-winged blackbirds had lower whole body selenium levels than did males, but levels in livers were higher. These differences may indicate some differences in foraging pattern or metabolism between the sexes. No doubt there are different metabolic requirements for males and females associated with reproduction. In general, one would expect metabolic requirements to be higher for females and thus one would expect selenium levels to also be higher in females.

Despite elevated selenium levels in the eggs, we failed to see any evidence of selenium induced reproductive failure or abnormality in any of the species studied. It is probable that our sample size was too small to document abnormalities even if they occurred. However, it is also possible that there were no abnormalities even though

selenium levels were high. Selenium in the lower Colorado River originates from cretaceous shale in the upper basin. Origin at this source makes it probable that selenium levels in the lower Colorado River have been chronically elevated perhaps over geological time. Birds nesting in the lower Colorado River could have been exposed to these elevated selenium levels over many generations and may have developed some resistance to the impacts of these levels that are not present in birds from other areas.

We saw no malformed chicks in the cliff swallow colony, but there was very high egg mortality. Destruction of eggs and chicks by conspecifics is a common phenomenon in cliff swallow colonies were there is intraspecific competition for resources (Rosenberg et al. 1991). In addition, virtually all nests were destroyed when causeway construction began in June. However, mortalities that occurred prior to June were not associated with construction.

This study would have been more conclusive if we could have taken more individuals of each species and taken representatives from each species from each habitat type. However, the permitting agencies – the Arizona Game and Fish Department and the U. S. Fish and Wildlife Service – would not permit us to take a larger sample size. We could not compare across habitat types because individual species nested in different habitats and thus we could not take representatives of each species from each habitat. We collected eggs and birds from the same nesting area so that we could directly compare levels in adults and eggs.
